

A Simple Effective Heuristic for Embedded Mixed-Integer Quadratic Programming

Reza Takapoui

Nicholas Moehle

Stephen Boyd

Alberto Bemporad

Abstract—In this paper we propose a fast optimization algorithm for approximately minimizing convex quadratic functions over the intersection of affine and separable constraints (*i.e.*, the Cartesian product of possibly nonconvex real sets). This problem class contains many NP-hard problems such as mixed-integer quadratic programming. Our heuristic is based on a variation of the alternating direction method of multipliers (ADMM), an algorithm for solving convex optimization problems. We discuss the favorable computational aspects of our algorithm, which allow it to run quickly even on very modest computational platforms such as embedded processors. We give several examples for which an approximate solution should be found very quickly, such as management of a hybrid-electric vehicle drivetrain. Our numerical experiments suggest that our method is very effective in finding a feasible point with small objective value; indeed, we see that in many cases, it finds the global solution.

I. INTRODUCTION

A. The problem

We consider the problem

$$\begin{aligned} & \text{minimize} && (1/2)x^T P x + q^T x + r \\ & \text{subject to} && A x = b \\ & && x \in \mathcal{X} \end{aligned} \quad (1)$$

with decision variable $x \in \mathbf{R}^n$. The problem parameters are the symmetric positive semidefinite matrix $P \in \mathbf{R}^{n \times n}$, the matrix $A \in \mathbf{R}^{m \times n}$, the vectors $b \in \mathbf{R}^m$ and $q \in \mathbf{R}^n$, and the real number $r \in \mathbf{R}$. The constraint set \mathcal{X} is the Cartesian product of (possibly nonconvex) real, closed, nonempty sets, *i.e.*, $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, where $\mathcal{X}_i \subseteq \mathbf{R}$ are closed, nonempty subsets of \mathbf{R} for $i = 1, \dots, n$. If \mathcal{X}_i is a convex set, we refer to variable x_i as a *convex variable*, and if \mathcal{X}_i is a nonconvex set, we call variable x_i a *nonconvex variable*.

Many problems can be put into the form of problem (1). For example, if some of the sets \mathcal{X}_i are subsets of integers, our formulation addresses mixed-integer quadratic and mixed-integer linear programs. This includes applications such as admission control [OCP07], economic dispatch [PF07], scheduling [CPM10], hybrid vehicle control [MJSB12], thermal unit commitment problems [CA06], and hybrid model predictive control [BM99].

If \mathcal{X} is a convex set, problem (1) is a convex optimization problem and can be readily solved using standard convex optimization techniques. Otherwise, the problem (1) can be hard in general. It trivially generalizes mixed-integer quadratic programming, an NP-complete problem, and can therefore be used to encode other NP-complete problems such as the traveling salesman problem [PS98], Boolean satisfiability [LZD04], [Kar72], set cover [Hoc82], and set packing [Pad73]. Hence, any algorithm that guarantees finding the global solution to (1) suffers from non-polynomial worst-case time complexity (unless $P = NP$).

B. Solve techniques

There are a variety of methods for solving (1) exactly. When all of the nonconvex sets \mathcal{X}_i in (1) are finite, the simplest method is brute force; enumerating through all possible combinations of discrete variables, solving a convex optimization problem for each possible combination, and finding the point with the smallest objective value. Other methods such as branch-and-bound [LW66] and branch-and-cut [SM99] are guaranteed to find the global solution. Special purpose methods have been introduced for some specific subclasses of (1). Unfortunately, these methods have non-polynomial worst-case runtime, and are often burdensome to use in practice, especially for embedded optimization, where runtime, memory limits, and code simplicity are prioritized. Also, these methods suffer from a large variance in the algorithm runtime.

On the other hand, many heuristics have been introduced that can deliver a good, but suboptimal (and possibly infeasible) point in a very short amount of time. For example, the *relax-and-round* heuristic consists of replacing each \mathcal{X}_i by its convex hull, solving the resulting relaxation (a convex quadratic program), and projecting the solution onto the nonconvex constraint sets. Another heuristic is to fix the nonconvex variables to several reasonable guess values and solve the convex optimization problem for convex variables. (Each of these methods may not find a feasible point, even if one exists.) The *feasibility pump* is a heuristic to find a

feasible solution to a generic mixed integer program and is discussed in [FGL05], [BFL07], [AB07]. Such heuristics are often quite effective, and can be implemented on very modest computational hardware, making them very attractive for embedded applications (even without any theoretical guarantees).

C. Embedded applications

We focus on embedded applications where finding a feasible point with relatively small objective value will often result in performance that is practically indistinguishable from implementing the global solution. In embedded applications, the computational resources are limited and a solution must be found in a small time. Hence, methods to find the global solution are not favorable, because their large variance in runtime cannot be tolerated.

In an embedded application, it is often required to solve several instances of (1), with different values of the parameters. Here we distinguish two separate use cases, depending on whether one or both of P or A change. This distinction will play an important role in solution methods. In the first use case, we solve many instances of (1) in which any of the parameters may change between instances. In the second use case, we solve instances of (1) in which q , b , and \mathcal{X} change between instances, but P and A are constant. Although this is more restrictive than the first use case, many applications can be well modeled using this approach, including linear, time-invariant model predictive control and moving horizon estimation. Indeed, all of the three examples we present in Section III are of this type.

D. Contributions

Our proposed algorithm is a simple and computationally efficient heuristic to find approximate solutions to problem (1) quickly. It is based on the alternating direction method of multipliers (ADMM), an algorithm for solving convex optimization problems. Because the problem class we address includes nonconvex optimization problems, our method is not guaranteed to find the global solution, or even converge.

Numerical experiments suggest that this heuristic is an effective tool to find the global solution in a variety of problem instances. Even if our method does not find the global solution, it usually finds a feasible point with reasonable objective value. This makes it effective for many embedded optimization applications, where finding a feasible point with relatively small objective value often results in performance that is practically indistinguishable from implementing the global solution.

An implementation of our algorithm along with numerical examples is available at www.github.com/cvxgrp/miqp_admm.

Comparison of the runtime with commercial solvers such as MOSEK [ApS15] and CPLEX [CPL09] show that our method can be substantially faster than solving a global optimization method, while having a competitive practical performance.

E. Related work

In recent years, much research has been devoted to solving moderately-sized convex optimization problems quickly (*i.e.*, in milliseconds or microseconds), possibly on embedded platforms. Examples include the SOCP solvers ECOS [DCB13], and FiordOs [UII11], and the QP solver CVXGEN [MB12]. Other algorithms have been developed exclusively for convex optimal control problems; see [WB10], [OSB13], [JGR⁺14]. In addition, recent advances in automatic code generation for convex optimization [MWB11], [CPDB13] can significantly reduce the cost and complexity of using an embedded solver. Some recent effort has been devoted to (globally) solving mixed-integer convex programs very quickly; see [Bem15], [FDM15] and references therein.

Even though ADMM was originally introduced as a tool for convex optimization problems, it turns out to be a powerful heuristic method even for NP-hard nonconvex problems [BPC⁺11, Sections 5, 9]. Recently, this tool has been used as a heuristic to find approximate solutions to nonconvex problems [CW13], [FJ15], [MWMA14]. In [DBEY13], the authors study the *Divide and Concur* algorithm as a special case of a message-passing version of the ADMM, and introduce a three weight version of this algorithm which greatly improves the performance for some nonconvex problems such as circle packing and the Sudoku puzzle.

II. OUR HEURISTIC

A. Algorithm

Our proposed algorithm is an extension of the alternating direction method of multipliers (ADMM) for constrained optimization to the nonconvex setting [BPC⁺11, Sections 5,9]. ADMM was originally introduced for solving convex problems, but practical evidence suggests that it can be an effective method to approximately solve some nonconvex problems as well. In order to use ADMM, we rewrite problem (1) as

$$\begin{aligned} & \text{minimize} && (1/2)x^T P x + q^T x + r + I_{\mathcal{X}}(z) \\ & \text{subject to} && \begin{bmatrix} A \\ I \end{bmatrix} x - \begin{bmatrix} 0 \\ I \end{bmatrix} z = \begin{bmatrix} b \\ 0 \end{bmatrix}. \end{aligned} \quad (2)$$

Here $I_{\mathcal{X}}$ denotes the indicator function of \mathcal{X} , so that $I_{\mathcal{X}}(x) = 0$ for $x \in \mathcal{X}$ and $I_{\mathcal{X}}(x) = \infty$ for $x \notin \mathcal{X}$. Each iteration in the algorithm consists of the following three steps:

$$x^{k+1/2} := \operatorname{argmin}_x \left((1/2)x^T P x + q^T x + r + \right. \quad (3)$$

$$\left. (\rho/2) \left\| \begin{bmatrix} A \\ I \end{bmatrix} x - \begin{bmatrix} 0 \\ I \end{bmatrix} x^k - \begin{bmatrix} b \\ 0 \end{bmatrix} + u^k \right\|_2^2 \right) \quad (4)$$

$$x^{k+1} := \Pi \left(x^{k+1/2} + \begin{bmatrix} 0 & I \end{bmatrix} u^k \right) \quad (5)$$

$$u^{k+1} := u^k + \begin{bmatrix} A \\ I \end{bmatrix} x^{k+1/2} - \begin{bmatrix} 0 \\ I \end{bmatrix} x^k - \begin{bmatrix} b \\ 0 \end{bmatrix}. \quad (6)$$

Here, Π denotes the projection onto \mathcal{X} . Note that if \mathcal{X} is not convex, the projection onto \mathcal{X} may not be unique; for our purposes, we only need that $\Pi(z) \in \operatorname{argmin}_{x \in \mathcal{X}} \|x - z\|_2$ for all $z \in \mathbf{R}^n$. Since \mathcal{X} is the Cartesian product of subsets of the real line, i.e., $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$, we can take $\Pi(z) = (\Pi_1(z_1), \dots, \Pi_n(z_n))$, where Π_i is a projection function onto \mathcal{X}_i . Usually evaluating $\Pi_i(z)$ is inexpensive; for example, if $\mathcal{X}_i = [\alpha, \beta]$ is an interval, $\Pi_i(z) = \min\{\max\{z, \alpha\}, \beta\}$. If \mathcal{X}_i is the set of integers, Π_i rounds its argument to the nearest integer. For any finite set \mathcal{X}_i with k elements, $\Pi_i(z)$ is a closest point to z that belongs to \mathcal{X}_i , which can be found by $\lceil \log_2 k \rceil$ comparisons.

B. Convergence

If the set \mathcal{X} is convex and problem (1) is feasible, the algorithm is guaranteed to converge to an optimal point [BPC⁺11, §3]. However, for \mathcal{X} nonconvex, there is no such guarantee. Indeed, because problem (1) can be NP-hard, any algorithm that finds the global solution suffers from nonpolynomial worst-case runtime. Our approach is to give up the accuracy and use methods that find an approximate solution in a small time.

Our numerical results verify that even for simple examples, the algorithm may fail to converge, converge to a suboptimal point, or fail to find a feasible point. Since the objective value need not decrease monotonically (or at all), it is critical to keep track of the best point found. That is, for a selected primal feasibility tolerance ϵ^{tol} , we shall reject all points x such that $\|Ax - b\| > \epsilon^{\text{tol}}$, and among those primal feasible points x that $\|Ax - b\| \leq \epsilon^{\text{tol}}$, we choose the point with the smallest objective value. Here, ϵ^{tol} is a tolerance for accepted feasibility. We should remind the reader again, that this point need not be the global minimum.

C. Initialization

To initialize x^0 , one can randomly choose a point in $\operatorname{Co} \mathcal{X}$, where $\operatorname{Co} \mathcal{X}$ denotes the convex hull of \mathcal{X} . More specifically, this means that we need to have access to a subroutine that generates random points in $\operatorname{Co} \mathcal{X}$. Our numerical results show that running the algorithm multiple times with different random initializations increases the chance of finding a feasible point with smaller objective value. Hence, we suggest running the algorithm multiple times initialized with random starting points and report the best point as the approximate solution. We always initialize $u^0 = 0$.

D. Computational cost

In this subsection, we make a few comments about the computational cost of each iteration. The first step involves minimizing a strongly convex quadratic function and is actually a linear operator. The point $x^{k+1/2}$ can be found by solving the following system of equations:

$$\begin{bmatrix} P + \rho I & A^T \\ A & -(1/\rho)I \end{bmatrix} \begin{bmatrix} x^{k+1/2} \\ v \end{bmatrix} = \begin{bmatrix} q' \\ 0 \end{bmatrix},$$

where $q' = -q + \rho(x^k + A^T b - [A^T \ I] u^k)$. Since the matrix on the lefthand side remains constant for all iterations, we can precompute the LDL^T factorization of this matrix once and cache the factorization for use in subsequent iterations. When P and A are dense, the factorization cost is $O(n^3)$, yet each subsequent iteration costs only $O(n^2)$. (Both factorization and solve costs can be significantly smaller if P or A is sparse.) Amortizing the factorization step over all iterations means that the first step is quite efficient. Also notice that the matrix on the lefthand side is quasi-definite and hence suitable for LDL^T factorization.

In many applications, P and A do not change across problem instances. In this case, for different problem instances, we solve (1) for the same P and A and varying b and q . This lets us use the same LDL^T factorization, which results in a significant saving in computation.

The second step involves projection onto $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_n$ and can typically be done much more quickly than the first step. It can be done in parallel since the projection onto \mathcal{X} can be found by projections onto \mathcal{X}_i for $i = 1, \dots, n$. The third step is simply a dual update and is computationally inexpensive.

E. Preconditioning

Both theoretical analysis and practical evidence suggest that the precision and convergence rate of first-order methods can be significantly improved by preconditioning the problem. Here, we use diagonal scal-

ing as preconditioning as discussed in [Bec14] and [WN99]. Diagonal scaling can be viewed as applying an appropriate linear transformation before running the algorithm. When the set \mathcal{X} is convex, the preconditioning can substantially affect the speed of convergence and is simply a tool to help the algorithm converge faster. Optimal choice of preconditioners, even in the convex case, is still an active research area [GB14a], [GB14b], [GTSJ15], [SLY⁺14], [HL12], [Bol13], [DY12]. In the nonconvex case, however, preconditioning can have a critical role in the *quality* of approximate solution, as well as the speed at which this solution is found.

Specifically, let $F \in \mathbf{R}^{n \times n}, E \in \mathbf{R}^{m \times m}$ be diagonal matrices with positive diagonal entries. The goal is to choose F and E to improve the convergence of ADMM on the preconditioned problem

$$\begin{aligned} & \text{minimize} && (1/2)x^T P x + q^T x + I_{\mathcal{X}}(z) \\ & \text{subject to} && \begin{bmatrix} EA \\ F \end{bmatrix} x - \begin{bmatrix} 0 \\ F \end{bmatrix} z = \begin{bmatrix} Eb \\ 0 \end{bmatrix}. \end{aligned} \quad (7)$$

The choice of E and F to minimize the effective condition number (the ratio of the largest singular value to the smallest non-zero singular value) of the following matrix is recommended in [GB14a]

$$\begin{bmatrix} E & 0 \\ 0 & F \end{bmatrix} \begin{bmatrix} A \\ I \end{bmatrix} P^\dagger \begin{bmatrix} A^T & I \end{bmatrix} \begin{bmatrix} E & 0 \\ 0 & F \end{bmatrix},$$

where P^\dagger denotes the pseudo-inverse of P . Given matrix $M \in \mathbf{R}^{n \times n}$, minimizing the condition number of DMD for diagonal $D \in \mathbf{R}^{n \times n}$ can be cast as a semidefinite program. However, a heuristic called *matrix equilibration* can be used to avoid the computational cost of solving a semidefinite program. (See [Slu69], [Bra10] and references therein.) Since for embedded applications computational resources are limited, we avoid finding P^\dagger or equilibrating completely. We instead find E to normalize the rows of A (usually in ℓ_1 or ℓ_2 norm) and set F to be the identity.

After finding E and F , preconditioned ADMM has the following form:

$$\begin{aligned} x^{k+1/2} &:= \begin{bmatrix} I & 0 \end{bmatrix} \begin{bmatrix} P + \rho F^2 & A^T E \\ EA & -(1/\rho)I \end{bmatrix}^{-1} \\ &\quad \begin{bmatrix} -q + \rho(F^2 x^k + A^T E^2 b - [A^T E \ F] u^k) \\ 0 \end{bmatrix} \\ x^{k+1} &:= \Pi \left(x^{k+1/2} + \begin{bmatrix} 0 & F^{-1} \end{bmatrix} u^k \right) \\ u^{k+1} &:= u^k + \begin{bmatrix} EA \\ F \end{bmatrix} x^{k+1/2} - \begin{bmatrix} 0 \\ F \end{bmatrix} x^k - \begin{bmatrix} Eb \\ 0 \end{bmatrix}. \end{aligned} \quad (8)$$

F. The overall algorithm

We use the update rules (8) for $k = 1, \dots, N$, where N denotes the (fixed) maximum number of iterations. Also, as described above, the algorithm is repeated for M number of random initializations. The computational cost of the algorithm consists of a factorization and MN matrix products and projections. A description of the overall algorithm is given in Algorithm 1, with $f(x) = (1/2)x^T P x + q^T x + r$.

Algorithm 1 Approximately solving nonconvex constrained QP (1)

```

if  $A$  or  $P$  changed then
  find  $E$  and  $F$  by equilibrating  $\begin{bmatrix} A \\ I \end{bmatrix} P^\dagger \begin{bmatrix} A^T & I \end{bmatrix}$ 
  find  $LDL^T$  factorization of  $\begin{bmatrix} P + \rho F^2 & A^T E \\ EA & -(1/\rho)I \end{bmatrix}$ 
end if
 $x_{\text{best}} := \emptyset, f(x_{\text{best}}) := \infty$ 
for random initialization  $1, 2, \dots, N$  do
  for iteration  $1, 2, \dots, M$  do
    update  $x$  from (8)
    if  $\|Ax - b\|_2 \leq \epsilon^{\text{tol}}$  and  $f(x) < f(x_{\text{best}})$  then
       $x_{\text{best}} = x$ 
    end if
  end for
end for
return  $x_{\text{best}}$ .

```

We mention a solution refinement technique here that can be used to find a solution with possibly better objective value after the algorithm stops. This technique, sometimes known as *polishing*, consists of fixing the nonconvex variable and solving the resulting convex optimization problem. Using this technique, one may use larger ϵ^{tol} during the N iterations and only reduce ϵ^{tol} at the refinement step. Depending on the application, it might be computationally sensible to solve the resulting convex optimization problem. Another effective technique is to introduce a notion of *no-good cut* during iterations for problems with binary variables. A no-good cut forces the vector of binary variables to change over iterations, by appending the linear equality constraint $\sum_{i \in T} x_i - \sum_{i \in F} x_i \leq B - 1$, to the minimization in the first step of (6), where we have $T = \{i \mid x_{b_i}^k = 1\}$ (i.e., T is the set of binary variables for which the last iterate was 1), $F = \{i \mid x_{b_i}^k = 0\}$, (i.e., F is the set of binary variables for which the last iterate was 0), and B is the number of elements of T . We do not use either of these techniques in the following examples.

III. NUMERICAL EXAMPLES

In this section, we explore the performance of our proposed algorithm on some example problems. For each example, ρ was chosen between 0.1 and 10 to yield good performance; all other algorithm parameters were kept constant. As a benchmark, we compare our results to the commercial solver MOSEK, which can globally solve MIQPs. All experiments were carried out on a system with two 3.06 GHz cores with 4 GB of RAM.

The results suggest that this heuristic is effective in finding approximate solutions for mixed integer quadratic programs.

A. Randomly generated QP

First we demonstrate the performance of our algorithm qualitatively for a random mixed-Boolean quadratic program. The matrix P in (1) was chosen as $P = QQ^T$, where the entries of $Q \in \mathbf{R}^{n \times n}$, as well as those of q and A , were drawn from a standard normal distribution. The constant r was chosen such that the optimal value of the unconstrained quadratic minimization is 0. The vector b was chosen as $b = Ax_0$, where $x_0 \in \mathcal{X}$ was chosen uniformly randomly, thus ensuring that the problem is feasible. We used $n = 200$ and $m = 50$ with $\mathcal{X}_i = \{0, 1\}$ for $i = 1, \dots, 100$, $\mathcal{X}_i = \mathbf{R}_+$ for $i = 101, \dots, 150$, and $\mathcal{X}_i = \mathbf{R}$ for the other indices i .

We used MOSEK to find the optimal value for the problem. After more than 16 hours MOSEK certifies that the optimal value is equal to 2040. We ran algorithm 1 for 10 different initializations and 200 iterations for each initialization, with step size $\rho = 0.5$. For a naive implementation in MATLAB, it took 120 milliseconds to complete all precomputations (preconditioning and factorization), and 800 milliseconds to do all 2000 iterations. The best objective value found for the problem was 2067 (1.3% suboptimal). Our implementation in C enables us to solve sparse problems significantly faster.

One interesting observation is that the parameter ρ tends to trade off feasibility and optimality: with small values of ρ , the algorithm often fails to find a feasible point, but feasible points found tend to have low objective value. On the other hand, with large values of ρ , feasible points are found more quickly, but tend to have higher objective value.

B. Hybrid vehicle control

We consider a simple hybrid electric vehicle drivetrain (similar to that of [BV04, Exercise 4.65]), which consists of a battery, an electric motor/generator, and a heat engine, in a parallel configuration. We assume that the demanded power P_t^{des} at the times $t = 0, \dots, T - 1$

is known in advance. Our task is to plan out the battery and engine power outputs P_t^{batt} and P_t^{eng} , for $t = 0, \dots, T - 1$, so that

$$P_t^{\text{batt}} + P_t^{\text{eng}} \geq P_t^{\text{des}}.$$

(Strict inequality above corresponds to braking.)

The battery has stored energy E_t at time t , which evolves according to

$$E_{t+1} = E_t - \tau P_t^{\text{batt}}, \quad t = 0, \dots, T - 1,$$

where τ is the length of each discretized time interval. The battery capacity is limited, so that $0 \leq E_t \leq E^{\text{max}}$ for all t , and the initial energy E_0 is known. We penalize the terminal energy state of the battery according to $g(E_T)$, where

$$g(E) = \eta(E^{\text{max}} - E)^2,$$

for $\eta \geq 0$.

At time t , the engine may be on or off, which is modeled with binary variable z_t . If the engine is on ($z_t = 1$), then we have $0 \leq P_t^{\text{eng}} \leq P^{\text{max}}$, and $\alpha(P_t^{\text{eng}})^2 + \beta P_t^{\text{eng}} + \gamma$ units of fuel are consumed, for nonnegative constants α , β , and γ . If the engine is off ($z_t = 0$), it consumes no fuel, and $P_t^{\text{eng}} = 0$. Because $z_t \in \{0, 1\}$, the power constraint can be written as $0 \leq P^{\text{eng}} \leq P^{\text{max}} z_t$, and the fuel cost as $f(P_t^{\text{eng}}, z_t)$, where

$$f(P, z) = \alpha P^2 + \beta P + \gamma z.$$

Additionally, we assume that turning the engine on after it has been off incurs a cost $\delta \geq 0$, *i.e.*, at each time t , we pay $\delta(z_t - z_{t-1})_+$, where $(\cdot)_+$ denotes the positive part.

The hybrid vehicle control problem can be formulated as

$$\begin{aligned} & \text{minimize} && \eta(E_T - E^{\text{max}})^2 + \sum_{t=0}^{T-1} f(P_t^{\text{eng}}, z_t) \\ & && + \delta(z_t - z_{t-1})_+ \\ & \text{subject to} && E_{t+1} = E_t - \tau P_t^{\text{batt}} \\ & && P_t^{\text{batt}} + P_t^{\text{eng}} \geq P_t^{\text{des}} \\ & && z_t \in \{0, 1\}, \end{aligned} \tag{9}$$

where all constraints must hold for $t = 0, \dots, T - 1$. The variables are P_t^{batt} , P_t^{eng} , and z_t for $t = 0, \dots, T - 1$, and E_t , for $t = 1, \dots, T$. In addition to the parameters given above, we take z_{-1} to be a parameter denoting the initial engine state.

We used the parameter values $\alpha = 1$, $\beta = 10$, $\gamma = 1.5$, $\delta = 10$, $\eta = 0.1$, $\tau = 5$, $P^{\text{max}} = 1$, $E^{\text{max}} = E_0 = 200$, and $z_{-1} = 0$. The demanded power trajectory P_t^{des} is not shown, but can be obtained by

Fig. 1: Engine power, battery power, battery energy, and engine on/off signals versus time. Left: the global solution. Right: the solution found using ADMM (Algorithm 1).

summing the engine power and battery power in Figure 1. We ran the algorithm with $\rho = 0.4$ for 900 iterations with primal optimality threshold $\epsilon^{\text{tol}} = 10^{-3}$. The global solution found by MOSEK generates an objective value of 139.52 and the best objective value with our algorithm was 140.07. In Figure 1, we see that qualitatively, the optimal trajectory and the trajectory generated by ADMM are very similar. Our implementation in C carries out precomputations in 27 milliseconds. The total time for all 900 iterations is 63 milliseconds, which gives each iteration an average time of 70 microseconds. MOSEK finds the first feasible point after 1 second, and it takes about 15 seconds to find a point with the same quality as found with our heuristic.

C. Signal decoding

We consider maximum-likelihood decoding of a message passed through a linear multiple-input and multiple-output (MIMO) channel. In particular, we have

$$y = Hx + v,$$

where $y \in \mathbf{R}^p$ is the message received, $H \in \mathbf{R}^{p \times n}$ is the channel matrix, $x \in \mathbf{R}^n$ is the message sent, and the elements of the noise vector $v \in \mathbf{R}^p$ are independent, identically distributed Gaussian random variables. We further assume that the elements of x belong to the *signal constellation* $\{-3, -1, 1, 3\}$. The maximum likelihood estimate of x is given by the solution to the problem

$$\begin{aligned} & \text{minimize} && \|H\hat{x} - y\|^2 \\ & \text{subject to} && \hat{x}_i \in \{-3, -1, 1, 3\}, \quad i = 1, \dots, n, \end{aligned} \quad (10)$$

where $\hat{x} \in \mathbf{R}^n$ is the variable.

We generate 1000 random problem instances with $H \in \mathbf{R}^{2000 \times 400}$ chosen from a standard normal distribution. The uncorrupted signal x is chosen uniformly randomly and the additive noise is Gaussian such that the

signal-to-noise ratio (SNR) is 8 dB. For such a problem in embedded application, branch-and-bound methods are not desirable due to their worst-case time complexity. We run the heuristic with only one initialization, with 10 iterations to find x^{admm} . The average runtime for each problem (including preprocessing) is 80 milliseconds, which is substantially faster than branch-and-bound based methods. Our numerical experiments show that in all test examples, the objective value found by x^{admm} is no worse than the one found by x^{rlx} . Also, we see that in 95% of the cases, the bit error rate using our heuristic was at least as good as the bit error rate (BER) using relax and round.

IV. CONCLUSIONS

In this paper, we introduced an effective heuristic for finding approximate solutions to convex quadratic minimization problems over the intersection of affine and nonconvex sets. Our heuristic is significantly faster than branch-and-bound algorithms and has shown effective in a variety of embedded problems including hybrid vehicle control and signal decoding.
